ABSTRACT

We consider the recovery of a finite stream of Dirac pulses at nonuniform locations, from noisy lowpass-filtered samples. We show that maximum-likelihood estimation of the unknown parameters can be formulated as structured low rank approximation of an appropriate matrix. To solve this difficult, believed NP-hard, problem, we propose a new heuristic iterative algorithm, based on a recently proposed splitting method for convex nonsmooth optimization. Although the algorithm comes, in absence of convexity, with no convergence proof, it converges in practice to a local solution, and even to the global solution of the problem, when the noise level is not too high. It is also fast and easy to implement.

Index Terms— Recovery of Dirac pulses, finite rate of innovation, maximum likelihood estimation, structured low rank approximation, optimization, Cadzow denoising

1. INTRODUCTION AND PROBLEM FORMULATION

Reconstruction of signals lying in shift-invariant spaces, including bandlimited signals and splines, has received long attention in sampling theory. Recently, analog reconstruction from discrete samples has been enlarged to a broader class of signals, with so-called finite rate of innovation (FRI), beyond the classical framework rooted in Shannon’s work [1, 2, 3].

In this paper, we focus on the retrieval of a finite stream of Dirac pulses from uniform, noisy, lowpass-filtered samples, a problem at the heart of the FRI theory [4, 1, 5, 6]. More precisely, the sought-after unknown signal s consists of K Dirac pulses in the finite interval [0, τ], where the real τ > 0 and the integer K ≥ 1 are known; that is

\[ s(t) = \sum_{k=1}^{K} a_k \delta(t - t_k), \quad \forall t \in [0, \tau], \quad (1) \]

\[ s^*(t) = \sum_{k=1}^{K} a_k \phi(t - t_k), \quad \forall t \in [0, \tau] \]

where \( \delta(t) \) is the Dirac mass distribution, \( \{t_k\}_{k=1}^{K} \) are the unknown distinct locations in \([0, \tau]\), and \( \{a_k\}_{k=1}^{K} \) are the unknown real nonzero amplitudes. The goal is to obtain estimates of these 2K values, which forms a deterministic (non-Bayesian) parametric estimation problem. The available data are, classically, linear uniform noisy measurements \( \{v_n\}_{n=0}^{N-1} \) on s, of the form

\[ v_n = \int_0^\tau s(t) \varphi \left( \frac{n \tau}{N} - t \right) dt + \varepsilon_n \quad (2) \]

\[ = \sum_{k=1}^{K} a_k \varphi \left( \frac{n \tau}{N} - t_k \right) + \varepsilon_n, \quad \forall n = 0, \ldots, N - 1, \quad (3) \]

where \( \varphi(t) \) is the sampling function and the \( \varepsilon_n \sim \mathcal{N}(0, \sigma^2) \) are independent random realizations of Gaussian noise. Note that other noise models could be considered as well, by changing the cost function in eqns. (5), (10), (14) below.

The questions of the choice of the function \( \varphi \) and of the number \( N \) of measurements allowing perfect reconstruction, in absence of noise, has been addressed in the literature [5, 6, 7]. In a nutshell, the condition \( N \geq 2K + 1 \), which we hereafter assume to be true, is necessary and sufficient, provided that \( \varphi \) satisfies some constraints in Fourier domain. In this work, as the emphasis is on appropriately handling the presence of noise, we adopt the simplest choice of the Dirichlet sampling function (which amounts to periodizing the signal s on the real line before sampling it with the sinc function):

\[ \varphi(t) = \frac{\sin(N \pi t / \tau)}{N \sin(\pi t / \tau)} = \frac{1}{N} \sum_{m=-M}^{M} e^{i 2 \pi m t / \tau}, \quad \forall t \in \mathbb{R}, \quad (4) \]

where hereafter we assume, without loss of generality and only to simplify the notations, that \( N \) is odd of the form \( N = 2M + 1 \). The extension of the setting to the reconstruction of pulses with real shape, instead of the ideal Dirac distribution, is of obvious practical interest in ultrawideband communications [2] or to detect impulsive signals in biomedical applications [5]. This extension, or equivalently the choice of another sampling function \( \varphi \), can be done without difficulty, as detailed in [5].
The paper is organized as follows. In Sect. 2, we formulate the maximum likelihood estimation problem and in Sect. 3, we show that it amounts to a low rank matrix approximation problem. The new algorithm to solve it is presented in Sect. 4.

2. MAXIMUM LIKELIHOOD ESTIMATION OF THE PARAMETERS

A natural approach to solve parametric estimation problem is maximum likelihood (ML) estimation; it consists in selecting the model which is the most likely to explain the observed noisy data. In our case, since we have supposed the noise to be Gaussian, this corresponds to solving the nonlinear least-squares problem [8]:

\[
\hat{\mathbf{a}} = \arg \min_{\mathbf{a} \in \mathbb{R}^K} \sum_{n=0}^{N-1} \left| v_n - \sum_{k=1}^{K} a_k e^{i \frac{2\pi n T k}{N}} \right|^2.
\]

Almost surely, the solution to this problem is unique, the obtained amplitudes \( \hat{a}_k = \{a_k\}_{K=1}^K \) are nonzero, and the obtained locations \( \hat{t}_k \) are distinct.

Now, applying the discrete Fourier transform to the vector of measurements yields the Fourier coefficients defined by

\[
\hat{v}_m = \sum_{n=0}^{N-1} v_n e^{-j 2\pi mn / N}, \quad \forall m = -M, \ldots, M.
\]

We define the Fourier coefficients \( \{\hat{\mathbf{v}}_m\}_{m=-M}^M \) similarly. Combining (3) and (4), we get, for every \( n = 0, \ldots, N-1, \)

\[
v_n - \varepsilon_n = \frac{1}{N} \sum_{k=1}^{K} a_k \sum_{m=-M}^{M} e^{j 2\pi m (n - t_k / \tau)}
\]

\[
= \frac{1}{N} \sum_{m=-M}^{M} e^{j 2\pi mn / N} \left( \sum_{k=1}^{K} a_k e^{-j 2\pi mt_k / \tau} \right).
\]

We recognize the form of the inverse discrete Fourier transform. Thus, by identification, we obtain

\[
\hat{v}_m = \sum_{k=1}^{K} a_k e^{-j 2\pi mt_k / \tau} + \hat{\mathbf{v}}_m, \quad \forall m = -M, \ldots, M.
\]

Since the inverse discrete Fourier transform is unitary, up to a constant, the problem (9) can be rewritten as [8]:

\[
\hat{\mathbf{v}} = \mathbf{T} \mathbf{a}, \quad \mathbf{T} = \left( \mathbf{I} + \frac{1}{N} \sum_{k=1}^{K} a_k e^{-j 2\pi mt_k / \tau} \right).
\]

We remark that (10) takes the form of a spectral estimation problem, which consists in retrieving the parameters of a sum of complex exponentials from noisy samples [9]. The optimal statistical properties of ML estimation for spectral estimation are well known [10, 11]. However, solving the problem (10) is a difficult task, as the cost function has a multimodal shape with many local minima [12, 13].

3. THE ANNIHILATION PROPERTY: REFORMULATION OF EQN. (10) AS A MATRIX APPROXIMATION PROBLEM

Let us assume temporarily that there is no noise, i.e. \( \hat{\mathbf{v}}_m = 0 \) in (9). Then, the sequence of Fourier coefficients \( \{\hat{v}_m\}_{m=-M}^M \) can be annihilated [21]; that is, its convolution with the sequence \( \{h_k\}_{k=0}^K \) is identically zero:

\[
\sum_{k=0}^{K} h_k \hat{v}_{m-k} = 0, \quad \forall m = -M + K, \ldots, M,
\]

where the Z-transform of the annihilating filter is defined, up to a constant, as

\[
H(z^{-1}) = \prod_{k=0}^{K} (1 - z^{-1} e^{j 2\pi t_k / \tau}).
\]

In matrix form, the annihilation property is

\[
\begin{bmatrix}
\hat{v}_{-M+K} & \cdots & \hat{v}_{-M} \\
\vdots & \ddots & \vdots \\
\hat{v}_M & \cdots & \hat{v}_{M-K}
\end{bmatrix}
\begin{bmatrix}
h_0 \\
h_K \\
0
\end{bmatrix} = \begin{bmatrix} 0 \\
\vdots \\
0 \end{bmatrix}.
\]

Let us define, for every integer \( P = K, \ldots, M \), the Toeplitz—i.e. with constant values along its diagonals—matrix \( \mathbf{T}_P \), of size \( N - P \times P + 1 \), obtained by arranging the values \( \{\hat{v}_m\}_{m=-M}^M \) in its first row and column; \( \mathbf{T}_K \) is depicted in (13). Then, the existence of an annihilating filter of size \( K + 1 \) for the sequence \( \{\hat{v}_m\}_{m=-M}^M \) is equivalent to the property that \( \mathbf{T}_P \) has rank at most \( K \), for every \( P = K, \ldots, M \).
Hence, turning back to the case when noise is present in the data, we can recast the estimation problem (10) as the following matrix approximation problem:

$$\text{Find } \mathbf{T}_p \in \text{arg min}_{\mathbf{T}' \in \mathbb{C}^{N-P \times P+1}} \| \mathbf{T}' - \mathbf{T}_p \|^2_w \quad \text{s. t. } \mathbf{T}' \text{ is Toeplitz and } \text{rank}(\mathbf{T}') \leq K,$$  \hspace{1cm} (14)

for some chosen $P \in K, \ldots, M$, where the weighted Frobenius norm of a matrix $\mathbf{A} = \{a_{i,j}\} \in \mathbb{C}^{N-P \times P+1}$ is defined by

$$\| \mathbf{A} \|^2_w = \sum_{i=1}^{N-P} \sum_{j=1}^{P+1} w_{i,j} |a_{i,j}|^2,$$ \hspace{1cm} (15)

where $w_{i,j}$ is the inverse of the size of the diagonal going through the position $(i, j)$:

$$w_{i,j} = \begin{cases} \frac{1}{(i-j+P+1)} & \text{if } i-j \leq 0, \\ \frac{1}{(P+1)} & \text{if } 1 \leq i-j \leq N-2P-1, \\ \frac{1}{(j-i+N-P)} & \text{if } i-j \geq N-2P. \end{cases}$$ \hspace{1cm} (16)

After the structured low rank approximation (SLRA) [22] problem (14) has been solved, the procedure to recover the estimates of the parameters is the following [1]. First, reshape the obtained Toeplitz matrix $\mathbf{T}_p$ to a Toeplitz matrix $\mathbf{T}_K$ of size $N-K \times K+1$; that is,

$$\mathbf{T}_K = \begin{pmatrix} \tilde{\mathbf{v}}_{-M+K} \cdots \tilde{\mathbf{v}}_{-M} \\ \vdots \ddots \vdots \\ \tilde{\mathbf{v}}_{M} \cdots \tilde{\mathbf{v}}_{M-K} \end{pmatrix}. \hspace{1cm} (17)$$

Second, compute the right singular vector $\tilde{\mathbf{h}} = \{\tilde{h}_k\}_{k=0}^K$ of $\mathbf{T}_K$ corresponding to the singular value 0. Since, almost surely, $\mathbf{T}_K$ has rank exactly $K$, $\tilde{\mathbf{h}}$ is unique, up to a constant. Third, compute the roots $\{\tilde{h}_k\}_{k=1}^K$ of the polynomial $\sum_{k=0}^K \tilde{h}_k z^k$; the estimates $\{\hat{t}_k\}_{k=1}^K$ of the locations are given by

$$\hat{t}_k = \frac{\tau}{2\pi} \text{arg}(0,2\pi(\hat{z}_k), \quad \forall k = 1, \ldots, K. \hspace{1cm} (18)$$

Fourth, given the estimates $\{\hat{t}_k\}_{k=1}^K$, the ML estimates $\{\hat{a}_k\}_{k=1}^K$ of the amplitudes are obtained by solving the linear system

$$\tilde{\mathbf{U}}^H \tilde{\mathbf{a}} = \tilde{\mathbf{U}}^H \hat{\mathbf{v}}, \hspace{1cm} (19)$$

where $\hat{\mathbf{v}} = [\hat{\mathbf{v}}_{-M} \cdots \hat{\mathbf{v}}_{M}]^T$, $^H$ denotes the Hermitian transpose, and

$$\tilde{\mathbf{U}} = \begin{pmatrix} e^{j2\pi M\hat{t}_1/\tau} & \cdots & e^{j2\pi M\hat{t}_K/\tau} \\ \vdots & \ddots & \vdots \\ e^{-j2\pi M\hat{t}_1/\tau} & \cdots & e^{-j2\pi M\hat{t}_K/\tau} \end{pmatrix}. \hspace{1cm} (20)$$

Thus, the process consists in denoising the matrix $\mathbf{T}_p$, or equivalently the data $\{v_n\}_{n=0}^{N-1}$, by finding the closest matrix consistent with the model’s structure, from which the parameters are estimated. In absence of noise, the parameters are perfectly recovered. The SLRA problem (14), which consists in projecting a matrix in the intersection of a linear subspace and a nonconvex manifold, is believed NP-hard [23, 24]. So, at first glance, we just have replaced the difficult problem (10) by the SLRA problem of same difficulty. However, there are several advantages with the latter. First, the estimation of the locations is decoupled from that of the amplitudes. Second, the initialization problem disappears: an iterative algorithm to solve (14) proceeds directly, with the noisy matrix $\mathbf{T}_p$ as initial estimate of the solution $\mathbf{T}_p$; moreover, for a low noise level, an algorithm converging to a local solution will find the global solution $\mathbf{T}_p$, as $\mathbf{T}_p$, $\mathbf{T}_p$ and the true noiseless matrix will correspond to the same catchment area of the cost function in (14).

We note that the obtained estimates $\{\{\hat{t}_k, \hat{a}_k\}\}_{k=1}^K$ coincide with the ML estimates, solution to (10), only if the roots $\{\tilde{z}_k\}_{k=1}^K$ are distinct and all on the complex unit circle. This is the case in practice, with high probability, if the noise level is not too high. Indeed, the matrices $\mathbf{T}_p$ and $\mathbf{T}_p$ are centro-Hermitian, i.e. their entries satisfy $\hat{\vartheta} = \hat{\vartheta}_m$ and $\hat{\vartheta}_m = \hat{\vartheta}_m$, for every $m$, where $^*$ denotes complex conjugation. Consequently, the polynomial $\sum_{k=0}^K \hat{h}_k z^k$ is self-inversive [25], so that its roots $\{\hat{z}_k\}_{k=1}^K$ are either on the complex unit circle or come by pairs with same complex phase and opposite amplitudes. In essence, when moving continuously the variables $\{v_n\}_{n=0}^{N-1}$ from their noiseless version to their actual noisy version, the corresponding estimated roots $\{\hat{z}_k = e^{j2\pi i_{\hat{t}_k}/\tau}\}_{k=1}^K$ deviate continuously from the true roots $\{z_k = e^{j2\pi i_{\hat{t}_k}/\tau}\}_{k=1}^K$, while remaining on the complex unit circle; only if the perturbation is large enough, two distinct roots $\{\hat{z}_k, \hat{z}_k\}$ will possibly merge and then split in a pair $\{\hat{z}_k, \hat{z}_k = 1/\hat{z}_k\}$ on both sides of the unit circle, yielding $\hat{t}_k = \hat{t}_k$.

We now briefly tackle the state of the art for solving SLRA problems, which have a wide range of applications [22, 26]. To our knowledge, the only publicly available software package for SLRA is the one currently in development by I. Markovsky [27]. However, it only handles real-valued, and not complex-valued, matrices. On the other hand, the popular heuristic Cadzow denoising method [28] is promoted in [1, 5] for our problem of recovering Dirac pulses. This algorithm denoises the matrix $\mathbf{T}_p$ iteratively: at each iteration, the matrix is replaced by its closest, in Frobenius norm, matrix of rank at most $K$, and then the obtained matrix is replaced by its closest Toeplitz matrix. If the algorithm converges, which is not guaranteed [29], it does so to a Toeplitz matrix of rank at most $K$, which is not even a local minimizer of the cost function $\| \cdot \|_w^2$ in (14) [12, 13]. In the next section, we propose a new algorithm to compute a local solution of the SLRA problem (14), which thus improves upon Cadzow denoising, for essentially the same complexity.
4. A NEW ITERATIVE OPTIMIZATION METHOD FOR SLRA

We consider the generic optimization problem:

\[
\text{Find } \tilde{x} \in \arg \min_{x \in \mathcal{H}} F(x) \quad \text{s.t.} \quad x \in \Omega_1 \cap \Omega_2, \tag{21}
\]

where \( \mathcal{H} \) is a real Hilbert space of finite dimension, \( \Omega_1 \) and \( \Omega_2 \) are two closed subsets of \( \mathcal{H} \), and \( F : \mathcal{H} \to \mathbb{R} \) is a convex and differentiable function with \( \beta \)-Lipschitz continuous gradient, for some \( \beta > 0 \); that is, \( \| \nabla F(x') - \nabla F(x) \| \leq \beta \| x - x' \| \), \( \forall x, x' \in \mathcal{H} \).

We denote by \( P_{\Omega_1} : \mathcal{H} \to \Omega \) the closest-point projection onto a closed set \( \Omega \subset \mathcal{H} \); that is, for every \( x \in \mathcal{H} \), \( P_{\Omega_1}(x) = \arg \min_{x' \in \Omega} \| x - x' \| \). If \( \Omega \) is convex, the minimizer in this definition is unique. The proposed algorithm to solve (21) is the following:

**Proposed algorithm.** Choose the parameters \( \mu > 0 \), \( \gamma \in [0, 1] \), and the initial estimates \( x^{(0)}, s^{(0)} \in \mathcal{H} \). Then iterate, for every \( i \geq 0 \),

\[
\begin{align*}
  x^{(i+1)} &= P_{\Omega_1} \left( s^{(i)} + \gamma (x^{(i)} - s^{(i)}) - \mu \nabla F(x^{(i)}) \right) \\
  s^{(i+1)} &= s^{(i)} - x^{(i+1)} + P_{\Omega_2} \left( 2 x^{(i+1)} - s^{(i)} \right)
\end{align*}
\]

The convergence result is a corollary of more general results derived in [30]:

**Theorem 1.** In (21), suppose that (i) a solution exists; (ii) the sets \( \Omega_1 \) and \( \Omega_2 \) are convex; (iii) \( r_1(\Omega_1) \cap r_1(\Omega_2) \neq \emptyset \), where \( r_1 \) denotes the relative interior. In the proposed algorithm, suppose that (iv) \( 2\gamma > \beta \mu \). Then, the sequence \( (x^{(i)})_{i \in \mathbb{N}} \) converges to some element \( \tilde{x} \) solution to the problem (21).

In absence of convexity, this result does not apply, so that we will use the method as a heuristic. The SLRA problem (14) can be recast as an instance of (21) as follows: \( \mathcal{H} = \mathbb{C}^{N - P \times P + 1} \) is the real Hilbert space of complex-valued matrices of size \( N - P \times P + 1 \) with centro-Hermitian symmetry, endowed with Frobenius inner product \( \langle X, X' \rangle = \sum_{i,j} x_{i,j} x'_{i,j} \); \( \Omega_1 \) is the closed nonconvex subset of \( \mathcal{H} \) of matrices with rank at most \( K \); \( P_{\Omega_1} \) corresponds to SVD truncation, according to the classical Schmidt-Eckart-Young theorem [31, theorem 2.5.3]: if a matrix \( X \) has SVD \( X = L \Sigma R^\mathsf{H} \), then \( P_{\Omega_1}(X) \) is obtained by setting to zero the singular values in \( \Sigma \), except the \( K \) largest; \( \Omega_2 \) is the linear subspace of \( \mathcal{H} \) of Toeplitz matrices; \( P_{\Omega_2} \) simply consists in averaging along the diagonals of the matrix; \( F(X) = \frac{1}{2} \| X - T_P \|_F^2 \), with \( \nabla F(X) = W \circ (X - T_P) \), where \( \circ \) is the entrywise (Hadamard) product and the entries \( \{ w_{i,j} \} \) of the matrix \( W \) are defined in (16), with Lipschitz constant \( \beta = \max\{ |w_{i,j}| \} = 1 \).

The proposed algorithm almost always converges: only when the noise level is very high, it possibly gets trapped in a cycle; but in that case, running again the algorithm with lower values of \( \mu \) and \( \gamma \) seems sufficient to obtain convergence. When the algorithm converges, it does so to a matrix in \( \Omega_1 \cap \Omega_2 \), which is a local minimizer of the cost function \( F \). In comparison with Cadzow denoising, we obtain estimation errors for the locations of the Dirac pulses, which are about 10% lower in average. An example of experimental setting with corresponding results is depicted in Fig. 1. More results are shown in the extended version of this article [32].

5. CONCLUSION

We showed that the maximum-likelihood estimation of the parameters of Dirac pulses from noisy lowpass-filtered samples can be recast as a structured low-rank approximation problem. We proposed a new heuristic optimization algorithm, which provides a local solution of the difficult nonconvex problem. Preliminary results show that it outperforms the state-of-the-art approach based on Cadzow denoising, for same ease of implementation and complexity, essentially one SVD per iteration. More in-depth analysis of the performances is currently led by the authors. A Matlab implementation is available on the webpage of the first author.
